ARTICLE INFO

ABSTRACT

We present in situ environmental transmission electron microscopy (ETEM) observation of metallic lithium nucleation, growth and shrinkage in a liquid confining cell, where protrusions are seen to grow from their roots or surfaces, depending on the overpotential. The rate of solid-electrolyte interface (SEI) formation affects root vs. surface growth mode, with the former akin to intermittent volcanic eruptions, giving kinked segments of nearly constant diameter. Upon delithiation, root-grown whiskers are highly unstable, because the segmental shrinkage rate depends on Li^+ transport across SEI, which is the greatest around the latest grown segment with the thinnest SEI, and therefore the near-root segment often dissolves first and the rest of the whisker then loses electrical contact. These electrically isolated dead lithium branches are also easily swept away into the bulk electrolyte to become "nano-lithium flotsam" because the hollowed-out SEI tube is very brittle. Our observations are consistent with SEI-obstructed growth by two competing mechanisms; surface growth of dense Eden-like clusters and root growth of whiskers, resulting from the voltage-dependent competition between lithium electrodeposition and SEI formation reactions. Similar phenomena could occur whenever chemical deposition/dissolution competes with irreversible side reactions that form a passivating layer on the evolving surface.

The lithium metal anode has an extremely high theoretical capacity (3800 Ah/kg) and low negative electrochemical potential (−3.04 V vs. standard hydrogen electrode). It has been extensively studied [1–4] since the lithium metal battery was first proposed in 1970s [5]. Despite its promising high energy density, rechargeable lithium metal batteries have not yet been commercialized successfully [6]. In contrast, the Li-ion battery with a graphite insertion anode is dominating markets ranging from portable electronics to electric vehicles and grid-scale energy storage [2,3].

A generic keyword explaining this history is "dendrite", although we will advocate for a more nuanced use of this term [7]. An initially smooth Li metal anode is prone to surface morphological instabilities in electrochemical cycling, forming extended protrusions that can cause not only dramatic loss of reversible capacity, but also penetration of the separator, short-circuiting, and in the worst cases overheating and thermal runaway [8]. Numerous researches have been conducted

in the last 40 years to understand the mechanisms and morphologies of Li metal growth, both experimentally [9–15] and theoretically [6,16–19], and methods to suppress the protrusions have also been proposed [2,20–25]. Generally, the morphology of the electrochemically deposited solid is affected by the current density and overpotential [26–28], and various qualitative theories have been developed to explain the growth mechanism [6]. Dendrites in solidification and phase transformation theory generally result from long-range *liquid-matrix* diffusion limitation, which causes thermal or chemical transport-induced instability at a smooth interface and leads to *tip growth* [29]. Dendrites in copper and zinc electrodeposition clearly result from diffusion-limited tip growth [30–34], so until recently, the "dendrites" that form at the Li metal anode were also believed to grow from the tips, despite occurring well below the long-range diffusion-limited current of the electrolyte [35–37]. Surprisingly, it was demonstrated by Dollé et al. through in-situ scanning electron microscopy (SEM) experiments using a polymer

---

electrolyte that dendrites could also grow from the root [38]. Similar *root growth* was observed by in-situ optical microscopy (OM) experiments using liquid electrolyte [7, 13,14]. Although different mechanisms have been suggested to explain the root growth [13,19], experimental investigation of the early stage of the nucleation and growth requires direct nanoscale observations. Here we reveal the essential roles of the liquid electrolyte *decomposition reaction* and SEI formation in the growth mode selection. In contrast to the liquid-state diffusion-limited growth of Cu and Zn dendrites, we show that, for typical operating currents, the growth and dissolution of Li "whiskers" and/or "mossy" deposits are modulated by *short-range solid-state diffusion* through the passivating SEI layer that is < 10 nm thin.

At the voltages we are considering, both Li^+ and the liquid electrolyte solvents are electrochemically unstable: they compete for electrons and co-deposit their reduction products (Li atoms and SEI constituents) wherever the electron sources may be. If the competition favors the latter, the SEI constituents may percolate and cover up the entire electron-donating surface (like CO poisoning of catalyst surface), which has two key consequences: (a) The Li^+ then has to diffuse across the SEI to be reduced, so Li atoms will deposit beneath the SEI, and (b) the SEI covering has mechanical strength, which will constrain such growth beneath, causing tensile stress in the SEI layer and compressive stress in the Li-metal beneath it. This stress balance will be broken when the SEI fractures at some location, forming a "fumarole" (taking a volcano analogy), while the compressive stress in the Li metal will drive an "atomic fountain", a Li whisker that shoots out of the fumarole by Nabarro-Herring or Coble creep (root growth), similar to how Sn whiskers form inadvertently in the microelectronics industry. If, on the other hand, the competition favors the former, then they will still be SEI patches here and there, but they do not connect or cannot seal up the growth front and Li atoms will grow around them, forming a mixture. In either case, because the liquid electrolyte solvents are electrochemically unstable and co-deposit with Li metal, their short-range interactions have to be carefully considered.

In-situ transmission electron microscopy (TEM) allows observations of electrochemical reactions at nanoscale in real time [39,40], originally with ionic liquid or solid electrolytes because of the high vacuum inside TEM. By sealing the volatile liquid electrolyte with two thin membrane windows that are electron-beam transparent [41–43], in-situ TEM observations of electrochemical reactions at common solid-liquid interface have been achieved [44–46], herein with our custom-built lab-on-a-chip mounted on standard TEM holder [47]. These methods have been applied to observe the formation/growth of the dendrites successfully [43,48]. However, only the tip growth mode was reported with ETEM. Understanding both the tip and the root growth modes is essential for achieving the following three levels of engineering goals for Li-metal anode, whose fulfillment is necessary for industry adoption: (A) total suppression of short circuiting across the separator, (B) improvement of Coulombic efficiency (reversibility of Li metal deposition) to 99.9% and above, and (C) reducing the speed of burning, upon breakage of battery cell and exposure to oxygen, in accident scenarios. Here we present in-situ ETEM observation of the root growth/shrinkage behavior of the lithium dendrite and fine-scale analysis of the process and its consequences, in different overpotential regimes. In addition to short-range solid-state interactions we have mentioned above, we can also observe change of chemistry in the liquid state and nanoscale flow fields around the evolving metal surface.

In order to conduct the in-situ ETEM experiment, we developed a liquid environmental electrochemical cell (LEEC) to prevent the evaporation of the volatile liquid electrolyte during TEM observations [47]. The device is schematically illustrated in Fig. 1(a). It consists of two silicon chips with 70 nm thick silicon nitride membrane windows. On one chip the gold electrodes were patterned on the window for observing the electrochemical redox reactions, and spacers were deposited to secure vertical gap space for the liquid electrolyte. On the opposite chip, a $LiCoO_2$ (LCO) film was deposited on an aluminum
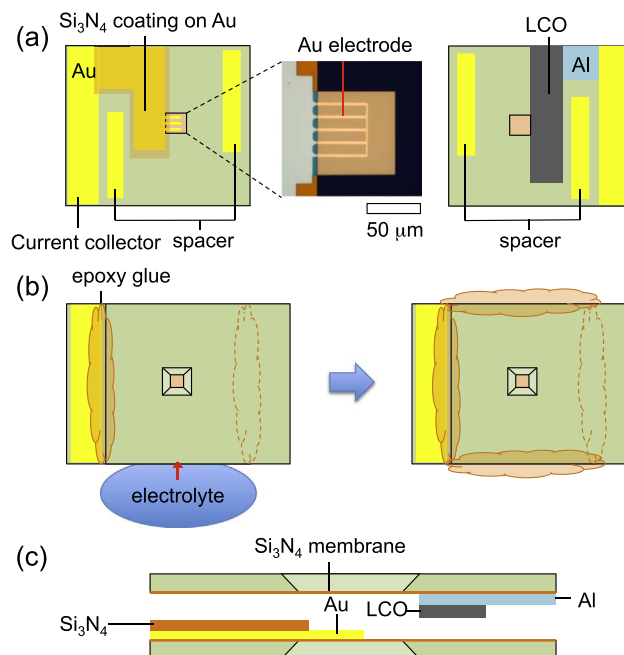

Fig. 1. (a) Schematic illustration of the liquid confining cell. The cell consists of two chips. The one with Au electrode patterned on the silicon nitride membrane has Au current collector coated with Si_3N_4 insulating layer to prevent the electrolyte exposure (left). The optical micrograph image is the magnified view of the Au electrode. $LiCoO_2$ (LCO) is sputtered on the Al film connected to the Au current collector as Li source (right). Both chips have Au spacers to secure a space for the electrolyte. (b) Procedure of the chip assembly. (c) Cross section view of the assembled cell near the silicon nitride membrane windows.

film as a lithium ion source. The detail of the device is explained in Supplementary information. The assembly process is described in Fig. 1(b). The two chips were stacked together and the two of the perimeter edges were sealed with epoxy glue. Liquid electrolyte was injected into the device by contacting the droplet to one of the opening (capillary action). Finally, the openings were sealed with epoxy glue. It is difficult to precisely evaluate the amount of electrolyte injected. However, it can be estimated to be on the order of nanoliter based on the geometry of the cell (see Supplementary information). The liquid injection and the final sealing were conducted in a glove box filled with argon gas. The electrolyte used in this work was a solution of 1 M lithium bis-trifluoromethanesulfonimide (LiTFSI) dissolved in dimethoxy sulfoxide (DMSO), one of the promising electrolytes for Li-air batteries [49] which use lithium metal as the anode. Fig. 1(c) shows the cross section of the device near the aligned viewing windows. Most of the electrode surface was insulated with silicon nitride to allow reaction only on the uninsulated gold electrodic region at the viewing window. We mounted the device on a Nanofactory scanning tunneling microscopy (STM) - TEM holder to apply bias voltage during TEM observation. A low dose rate of 1.3 $e^-/Å^2s$ was used to minimize the beam damage to the electrolyte, and the images were captured in the TEM bright-field mode.

Fig. 2(a) shows sequential TEM images of the electrodeposition process on gold biased at −4.5 V vs. the LCO counter electrode, which drives lithium metal deposition and non-uniform protrusions (see also Supplementary Movie S1). Because the typical plateau charging potential of LCO starts at ~3.9 V vs Li^+/Li, the total local overpotential is around 3.9–4.5≈−0.6 V vs Li^+/Li, much of which is likely transferred to the surface by the highly ion-conductive liquid electrolyte (see below), so the driving force for lithium metal deposition is quite high. Also, the liquid electrolyte is very unstable at this potential [8] and will decompose by reduction to form SEI constituents on any newly exposed electron-conductive surface. We observed that small spherical lithium domains first appear on the surface of the gold electrode and
Fig. 2. (a) Sequential TEM images of the Li whisker growth at −4.5 V vs. LCO (Supplementary Movie S1). (b) Change in the electric current during the lithium deposition. (c) Close up view of a single Li hair growth process indicated by the arrowhead in (a).

then start to evolve into long whiskers that grow like hair from their roots at the electrode interface, in contrast to the tip growth of conventional dendrites in solidification and copper electrodeposition. The electric current during the deposition is shown in Fig. 2(b). Although there is a high initial current, it remains almost constant ~20 nA. Based on the electrode geometry (see Supplementary information), this corresponds to the current density of ~2.8 mA/cm^2. Fig. 2(c) is the magnified view of the growth process of the single lithium "hair" or "whisker" indicated by the arrowhead in Fig. 2(a). The shape of the tip as well as the width of the whisker remain the same throughout the growth process, which is a clear sign of root growth. The whisker growth direction also intermittently changed by forming kinks, consistent with the ex-situ SEM observation of the lithium whiskers formed by the root growth mechanism [38].

The whiskers started to dissolve and shrink after the bias potential was switched to 1.0 V vs. LCO. Fig. 3(a) shows the sequential TEM images during the dissolution (see also Supplementary Movie S2). The whiskers rapidly dissolved in the first 15 s, and their morphology did not change henceforth. Some of the pieces apparently become electrically disconnected and isolated from the electrode (dead volume). Thereafter, electro-osmotic flows of the electrolyte swept away these isolated remnants, leaving only a few attached to the electrode, as shown in the area marked by the dashed line in the figure. The change in the electric current during dissolution is shown in Fig. 3(b). The current decreased rapidly and became nearly zero after 20 s. This together with the in-situ TEM observation indicates that the dissolution of the lithium whiskers created electrically isolated "dead lithium", causing irreversible capacity loss in the deposition/dissolution cycling process. Some fragments were weakly attached to the electrode and easily swept away into the electrolyte, while others remained on the electrode but were electrically inactive. Since by then no electric current was observed as the lithium whiskers stopped shrinking, the pieces of the lithium left on the electrode were likely connected only by the hollowed-out SEI tubes, which are electrically insulating. From the current vs. time plots shown in Figs. 2(b) and 3(b), we estimated the Coulombic efficiency to be ~20% with the discharge and the charge
Fig. 3. (a) Dissolution process of the Li whisker at 1.0 V vs. LCO biasing (Supplementary Movie S2). The lithium hair dissolved rapidly in the first 20 s and the rate became significantly slower at $t > 20$ s. A piece of Li marked in the dashed line was swept away into the electrolyte. (b) Change in the electrical current during the Li dissolution. The fast decay of the current corresponds to the Li dissolution at $t < 20$ s.

capacity of 7.7 μC and 1.6 μC, respectively.

Fig. 4(a) shows the nucleation and growth of another single lithium whisker in a higher magnification TEM observation (see also Supplementary Movie S3), at −6.0 V vs LCO. Sequential high-resolution TEM images allow us to perform detailed analysis of the reaction kinetics. The initially formed whisker Λ was separated into two segments Λ1 and Λ2, with Λ2 pushing Λ1 along the direction indicated by the arrow (see schematics below the TEM images). Fig. 4(b) shows the change in the length and the width of the whisker Λ (Λ → Λ1, Λ2 after the kink formation) during electrodeposition. The whisker growth process can be separated into four distinct stages, based on a quantitative analysis of the TEM movies:

STAGE I: A spherical lithium nucleus emerged at the surface and grew with its diameter proportional to the square root of the time, indicating diffusion limitation, which we associate below with short-range solid-state transport through the SEI layer, rather than long-range liquid-state diffusion. The SEI layer passivates the surface and gradually reduces the lithium deposition rate, since Li⁺ ions need to diffuse across the thickening SEI film that covers the surface.

STAGE II: The lithium whisker started to grow from its root pushing the initially formed sphere away from the electrode. Here a

rapid increase in the length of the whisker L was observed, while its width remained almost constant. A dramatic upturn in lithium deposition rate between stage I and II indicates some kind of abrupt transition, akin to intermittent stick-slip dynamics in friction.

STAGE III: The growth rate decreased significantly, which can be attributed to the formation/thickening of the SEI covering layer on the newly formed portion of the whisker.

STAGE IV: A kink was formed on the whisker separating it into two segments L1 and L2. Newly formed segment L2 grew from the root and pushed the preexisting portion of the whisker in the direction different from the growth direction of L (a kink formation). While L2 increased its length and the width, L1 length remained unchanged. Note that the growth rate of the L2 was close to that of L and the width of the L2 was saturated to the same value with L1. Such intermittent kinked growth then repeats quasi-randomly.

A quantitative analysis of the growth mechanisms was performed based on the TEM movies. In Stage I, a small spherical lithium seed was formed at the location marked by the open arrowhead in the figure. The sphere grew larger during the deposition, but the growth rate gradually decreased. The size of the sphere grew roughly as the square root of time, $h(t) = h_1(t/\tau_1)^{1/2}$, where $h_1 = 300$ nm and $\tau_1 = 25$s. The observed size can be converted to a decaying, uniform current density,

$I(t) = I_1(\tau_1/t)^{1/2}$, where $I_1 = c_{Li}Fh_1/2\tau_1 = 4.8$ mA/cm^2 , using Faraday's constant, $F = 96,485$ As/mol , and the lithium metal concentration, c_{Li}=0.534 g/cm^3 /6.491 g/mol =82 M.

Square-root scaling with time strongly suggests diffusion limitation, but does not reveal the rate-limiting transport process. All existing models for the growth of "dendrites" assume liquid electrolyte diffusion limitation, but this is clearly impossible at the nanoscale. The steady limiting current density on the whisker nucleus, modeled as a hemispherical ultra-microelectrode [50], $I_{lim} = 2Fc_0D_{app}/h_1 = 19$ A/cm^2 , is 5000 times larger the observed current density,I_1 ($c_0 = 1M$, $D_{app} = 3 \times 10^{-6}$ cm^2/s[51]). Moreover, the relaxation time for electrolyte diffusion, $\tau_{lim} = h_1^2/D_{app} = 0.3$ ms , is 10,000 times smaller than the growth time τ_1. On the other hand, the measured current I_1 at the end of spherical growth is only somewhat larger than reported exchange currents for electron-transfer reactions at lithium metal films [52], $I_0 = 0.1 - 2.0$ mA/cm^2. Overall, we conclude the lithium growth processes observed in our experiments are all *macroscopically reaction-limited* at the electrode/electrolyte interface, although the local reaction rate can be *microscopically diffusion-limited* by transport processes within the solid-state interface layers.

As noted above, the slowing down of the initial surface growth rate is likely related to rapid SEI formation, which competes with lithium electrodeposition and hinders Li$^+$ transport. It is well established that capacity fade in Li-ion batteries exhibits square-root-time scaling due to rate-limiting solvent diffusion across the SEI layer on porous carbon [37,53–55], but this process (by itself) is too slow to play a role in the early stages of lithium metal growth. Using the fitted solvent diffusivity in SEI on carbon in similar electrolytes, D_{sol}^{SEI}~3×10^{-17} cm^2/s[54,55] (or ~10^{-19} cm^2/s[53]), the solvent penetration depth in our experiments would be at the single-molecule scale, $\sqrt{2D_{sol}^{SEI}\tau_1} = 0.4$ nm (or 0.02 nm). This is clearly too thin compared to the solid SEI we observed forming directly in TEM (more on this later), which was ~10nm. Thus we revise D_{sol}^{SEI} upward to 2×10^{-14} cm^2/s in the initial stage of SEI formation. We then propose that Li$^+$ diffusion through the growing SEI (full coverage) limits the local reaction rate and leads to square-root-of-time scaling at early times.

To test this hypothesis quantitatively, we formulate a simple model for the coupled rates of electrodeposition and SEI formation. The Li metal surface growth is limited by Li$^+$ diffusion through the SEI film of thickness, $s(t)$, whose growth is limited by solvent diffusion through the same SEI film,

$$c_{Li}\frac{dh}{dt} = \frac{D_{Li^+}^{SEI}c_0}{s}, \quad c_{SEI}\frac{ds}{dt} = \frac{D_{sol}^{SEI}c_{sol}}{s} \Rightarrow h(t) = \frac{D_{Li^+}^{SEI}c_0}{c_{Li}}\sqrt{\frac{2c_{SEI}t}{D_{sol}c_{sol}}}$$

Assuming similar solvent concentrations in the SEI and bulk solution, $c_{SEI} \approx c_{sol}$, we can use the experimentally observed Li growth rate to estimate the Li$^+$ diffusivity in SEI as $D_{Li^+}^{SEI}$~2×10^{-12} cm^2/s , which to our knowledge has not previously been measured. This is a reasonable value, much larger than the solvent diffusivity in SEI (on carbon), D_{sol}^{SEI}, and much smaller than the apparent salt diffusivity in the liquid electrolyte [51], D_{app}. Although these estimates establish the relative magnitudes of different transport processes, we note that the standard diffusion equation may not apply at very small $s(t)$, and electric field driven transport like Cabrera-Mott kinetics [57] may predict a much more rapid (inverse logarithmic) growth of $s(t)$ at the earliest stage of growth, beyond the resolution of the experiments.

After the initial spherical surface growth, the lithium metal protruded out from the electrode and rapidly formed a whisker at t ~30 s. During this stage of growth, a fragment of the electrode (marked by the open arrowhead) was rapidly pushed away from the electrode. This indicates that the growth point of the whisker was at the root, possibly subsurface [58]. The limiting whisker growth rate corresponds to a mean current density, $I_2 = 42$ mA/cm^2, over the root area, if it were by electrochemical deposition. This observed value is much larger than the SEI-limited current, I_1, and macroscopic exchange current, I_0, which

indicates that bursts of root growth must be temporarily uninhibited by SEI. This may also indicate that such bursts may rely not only on absorbing Li$^+$ from the outside, but also on the redistribution of existing Li-atoms beneath the surface, e.g. by relaxation of residual compressive stress by solid-state Nabarro-Herring or Coble creep.

Consistent with this interpretation, the fast root growth was observed to be intermittent. After the whisker became ~1.0 μm in length at t~45 s, it ceased to grow further, and then suddenly at t ~60 s it grew at approximately the same rate ($I_2 = 42$ mA/cm^2) in a different direction, forming a kink. Our observations of intermittent root growth with kink formation agrees with reported SEM images of the root-grown lithium whiskers [13,38]. It is worth noting that the kink may also be a new growth point [13], although we did not observe any clear sign of protrusions growing at the kink, possibly because our in-situ TEM experiment was focused at the limited viewing area capturing the initial state of the whisker nucleation/growth. Longer deposition time and viewing at lower magnification may allow us to capture the kink branching mechanism.

In our ETEM (see e.g. Supplementary Movie S3), we can clearly see a gradual darkening of the liquid electrolyte around a newly protruded lithium hair/whisker, of initial depth scale ~10^2 nm (Fig. 4a), which eventually sharpens to a ~10^1 nm or even sub-10 nm dark skin layer (Fig. 4a) surrounding the low density lithium-metal whisker, as the bright-field TEM image contrast originates mostly from mass-thickness. The density of lithium is 0.534 g/cm^3 which is about one half of DMSO electrolyte (1.10 g/cm^3). We interpret this as liquid electrolyte decomposition by accepting electrons from the electrode, and subsequent formation of SEI constituents that contains LiF (2.64 g/cm^3), Li$_2$O (2.01 g/cm^3), etc. with higher salt concentration and average density than the Li metal and the original electrolyte solution. The contrast and the resolution of the ETEM images are also affected by the thickness of the liquid layer in the cell. A thick layer of electrolyte reduces the contrast and the image resolution. In Fig. 4, contrast/resolution was better than those in Fig. 2 because electrolyte was wetting only the surface of the electrode (Supplementary information Fig. S5). In Fig. 2 (see also Supporting Movie S1 and S2), the image resolution was partially improved when the gas pushed the electrolyte away from the view.

From the ETEM observations, we believe the initial SEI at stage I may be critical for the root protrusion mode above, because a stress-induced breakage of SEI passivation layer at stage I-to-II transition may give a hole (like fumarole in volcano) that templates future extrusion, which explains the nearly constant width of the whisker in stage II-IV, as it has to protrude out of the same hole on the SEI layer.

After the voltage was switched to dissolve the lithium metal whiskers (lithium stripping), the shrinkage took place mostly at the newer segment formed at later stages as shown in Fig. 4(c) (see also Supplementary Movie S4). This can be explained by the variation of the SEI thickness on the whisker. At the voltage range we are considering, liquid electrolyte decomposition and formation of SEI is unavoidable on any surface that conducts electrons [8]. Since the newly formed segment Λ2 had thinner SEI than Λ1, lithium ion diffusion out to the electrolyte happens faster at Λ2 and dissolution preferentially took place at Λ2. The consequence is that the lithium segment near the root hollowed out, leaving an empty SEI shell tube that electrically disconnect the tip part from the base electrode. This created an electrically inactive lithium metal volume ("dead lithium") above the hollow SEI shell tube that could not be dissolved further. This isolated lithium was eventually swept away into the electrolyte, since the hollowed-out SEI tube stems are apparently quite brittle. The reason for the liquid electrolyte convective flow at small scale could be heating-induced convection, electroosmotic / electrocapillary forces, dielectrophoretic electric field induced membrane bending, etc. We believe such micro-flows are ubiquitous and unavoidable in real batteries, and so the nano-lithium/SEI segments that get broken and entrained into the electrolyte then become nano-lithium flotsam in real batteries.
Fig. 5. (a) Lithiation of the gold electrode at −3.5 V vs. LCO (Supplementary Movie S5). The lithiation was randomly initiated as indicated by the arrowheads and propagated inhomogeneously across the electrode (the boundaries are marked by the dashed lines). (b) Dense lithium grown on the gold electrode at −4.0 V vs. LCO (Supplementary Movie S6). The morphology of the surface changed as in the growth process (marked by the arrowheads), indicating the deposition took place at the surface.

Macroscopically, when we open up a secondary battery with lithium metal anode after cycling, we see the originally white separator wet by liquid electrolyte becomes darker colored and has a "dirty" appearance. We think this is because the pores of the separator with liquid electrolyte are filled with these nano-lithium flotsams, which have huge surface area. In an accident with breached packaging (level C engineering goal for Li-metal anode mentioned earlier), when these nano-lithium flotsams are exposed to oxygen, we believe it increases the fire risks. The nano-lithium flotsam may also drift to the counter electrode by Brownian motion and cause spontaneous discharge and high temperature spots.

In this work we have used a gold electrode for lithium deposition due to the ease of fabrication. However, lithium should react with gold to form Au-Li intermetallics at an equilibrium voltage of ~0.4 V vs Li$^+$/ Li [59]. Indeed in our experiments, lithiation of the gold electrode can be clearly observed when −3.5 V vs. LCO was applied, as shown in Fig. 5(a) (see also Supplementary Movie S5). This data point of ours is roughly consistent with the literature because the typical plateau charging potential of LCO cathode is ~3.9 V vs Li$^+$/Li, so 3.9– 3.5≈0.4 V. In our in-situ liquid cell experiments, the areas with lighter contrast in Fig. 5 are the lithiated Au-Li nanodomains. Such Au-Li lithiation nanodomains propagated across the electrode inhomogeneously similar to that reported by Zeng et al. [60].

In stark contrast, we did not observe lithiation of the gold electrode itself or Au-Li nanodomains when lithium metal was deposited through the root growth mode as shown in Figs. 2 and 4, where large overpotentials (−4.5 V and −6.0 V vs. LCO) were applied. Strangely, the gold electrode appeared inert. Such large overpotentials may promote the formation of denser, thicker SEI on the Au surface, which reduces the rate of Au-Li formation despite a larger thermodynamic driving force of forming Au-Li compared to Fig. 5(a) case, which could be a kinetic passivation effect like the anodic-protection passivity regime in metal corrosion. The denser and thicker initial SEI is also
Fig. 6. Schematic illustration explaining root growth mechanism of lithium whiskers.

inductive to causing stress build-up, as the SEI patches tend to connect up and cover the electron-donating surfaces completely, promoting the root growth mode (see Fig. 6). Once the initial SEI are punctured due to stress at stage I-to-II transition, and a hole formed like the "fumarole" of a volcano, the kinetics seems to favor direct lithium metal deposition at the root, instead of Au-Li formation. Although Au-Li can be formed at any time afterwards by chemical reaction according to thermodynamics, we do not actually see Au-Li formation in ETEM, but relatively faster Li deposition rate at the fumarole instead.
The above phenomena may be attributable to a liquid | SEI1 | SEI0 | Au interfacial structure, similar to the bilayer SEI model for carbon electrodes [37,61–63], where SEI1 is conductive to Li$^+$ but not electrons (like the conventional SEI), and SEI0 is conductive to electrons but not Li$^+$ ion or Li atom (unconventional SEI, playing a role similar to the anodic-protection passivation layer in metal corrosion). If we accept this hypothetical two-layer SEI structure, the nucleation and growth of Lithium metal should occur at SEI1 | SEI0 interface (the "root"). According to this picture, Au-Li formation is kinetically throttled by SEI0 because SEI0 does not conduct Li$^+$ ion or Li atom, and SEI0 forms only at high overpotentials (−4.5 V and −6.0 V vs. LCO).

The lithium growth mode was distinctly different when an intermediate potential (−4.0 V vs. LCO) was applied. Fig. 5(b) shows the deposition process (see also Supplementary Movie S6). At this potential, growth occurs fairly uniformly over the surfaces, resulting in dense clusters of random surface growth similar to the Eden model [64], only

smoother due to surface tension and surface diffusion. The bud-like protrusions initially resemble the spherical nucleus of Fig. 4 in Stage I, but rather than erupting into narrow whiskers (Stages II-IV), these structures keep growing in all directions and until they become crowded on the surface like cauliflower, and then have to grow outward. At such an intermediate overpotential, the decomposition rate of the liquid electrolyte can be decreased and becomes slower than the lithium deposition rate, and Li metal grows from the surface instead of the root. Nonetheless, we expect some disconnected SEI molecular fragments mixed in with the growing lithium metal. Finite rates for both reactions could be added to the Li/SEI growth model above, leading to a gradual linear (not square-root) current increase at early times [54]. This implies that the relationship between the SEI formation and the lithium deposition rates is important for determining the Surface vs. Root growth mode. The two modes actually give very distinct morphologies: the root growth mode gives relatively sparsely separated lithium "hairs" or "whiskers" with constant widths, while the surface growth mode (Fig. 5b) gives dense "buds" that can easily grow in width as well as length, so that they end up densely packed in the lateral direction like cauliflowers. It is important to stress these *dense "mossy" structures are not true "dendrites"*, which are sparse, branched fractal structures caused by electrolyte diffusion limitation ahead of the tips [7], as observed in copper electrodeposition or solidification. As noted above, lithium growth cannot be limited by liquid-state electrolyte diffusion at these length and time scales and is instead determined by local interfacial kinetics (including diffusion in the SEI film). Our observation reveals that the fast growing SEI at high overpotential confines the lithium causing the stress build-up that leads to the root growth of the lithium whiskers. On the other hand, the SEI growth rate is not high enough at low overpotential, and SEI may co-deposit with lithium metal to allow electrons to reach the surface, hence the surface growth.

From the observations and analyses above, we suggest the following root growth mechanism in electrodeposition and subsequent shrinkage of the lithium whiskers in electrostripping as schematically shown in Fig. 6. At potential below −0.5 V vs Li⁺/Li, lithium starts to deposit at the SEI1 | SEI0 interface, preferentially at a nucleation site where SEI0 is thinner, and forms a spherical bud by surface growth, hindered by SEI1 (Stage I). While such an "inverted" SEI0 layer (stopping Li and not electrons) runs contrary to conventional notions about SEI, it has been postulated for carbon anodes [37,61–63] and is consistent with the absence of the Au-Li nanodomains in our experiments at large overpotentials (−4.5 V and −6.0 V vs. LCO). We therefore propose that SEI0 would form in DMSO/LiTFSI electrolyte when the electrode potential drops below −0.5 V vs Li⁺/Li. Some SEI0 may also form on the fresh surface and contribute to reducing the growth rate and hardening of the SEI1 film. The net result is that compressive stress arises underneath. When the stress reaches a threshold, SEI1 covering can no longer sustain the stress, especially along the sides near the root. The punctured hole on the initially flat SEI1 acts as the "fumarole" of the volcano, and templates further growth. Lithium then sponta-neously breaks out and pushes the top to form a whisker (Stage II), vaguely analogous to the seismic triggering of volcano activities. During this burst of growth, the root may slightly separate from the original SEI0 base, so that fresh lithium can freely diffuse and deposit under the root, causing the whisker to extend. Solvent molecules are too large and slow to diffuse into the root to hinder electrodeposition, but as the compressive stress is relaxed, the whisker growth stops (Stage III). The process then repeats itself, as further stress increase leads to another SEI1 film rupture and root growth of the next whisker segment (Stage IV).

A summary of at least 3 modes of lithium metal/SEI fragment deposition seen to date is shown in Fig. 7. In this work we distin-guished two different growth mechanisms by in-situ liquid cell TEM: Reaction limited surface growth (Mode I) and competing SEI formation leading to whisker growth (Mode II). The transition from these

Mode III: Electrolyte diffusion limited, **Li dendrites**, rapid tip growth, **break out post** Sand's time [7]

Mode II: Competing SEI reaction, **Li whisker, root growth,** compressive stress buildup/release

Mode I: Reaction limited, **dense surface growth**, Cauliflower or Eden cluster like

Fig. 7. Comparison of at least 3 modes of Lithium deposition seen to date. Mode I: Dense surface growth, cauliflower or Eden cluster like (taken from Fig.5b and Supplementary Movie S6), possibly a mixture of tip and root growth at larger scales. Mode II: Lithium whisker, pure root growth (taken from Fig.4a and Supplementary Movie S3). The whisker's root growth is driven by complete SEI coverage, compressive stress buildup and repeated stress relaxation through the hole at the root. Mode III: lithium dendrite, whose rapid breakout is seen only after Sand's time is reached and pure tip growth (taken from [7]).

reaction limited process to the electrolyte diffusion limited process can occur forming true "dendrites" (Mode III) [7]. Our observations may give insights to controlling the reaction limiting process at the early stage of lithium electrodeposition. Besides the applied potential, various factors can affect the relative rates of lithium electrodeposition and SEI decomposition, and the composition of the SEI, such as the operating temperature, electrolyte compositions, electrode materials, and the surface roughness. Extensive parametric studies will be required to understand the complex interactions of these factors and quantitatively predict the lithium deposition mechanism (Surface vs. Root) and rate. This is a complex nonlinear problem in chemo-mechanics leading to intermittent growth, similar to stick-slip motion in friction. A subsurface compressive stress is known to be a driving force to form Sn whiskers on a substrate [65–67]. The dominant direction of the residual stress accumulated subsurface may change from time period to time period due to changing boundary conditions, inducing stop-and-go, time-dependent "thrust" directions and forma-tion of kinks. Because the bulk melting point T_M of lithium metal is 454 K, at room temperature T/T_M =0.66, surface and/or lattice diffusion of lithium atoms is expected to be facile. Therefore the root growth of lithium hair driven by subsurface compressive stress may be well described by linear-response Coble/Nabarro-Herring diffusional creep theory [68,69] It was also reported for lithium that a subsurface structure may be responsible for dendrite nucleation [58].

Because of the time lag between the formations of the whisker segments, the thickness of the SEI formed on the whisker can vary, and the dissolution is expected to be faster where the SEI is thinner. This causes regions near the electrode to be the primary sites of dissolution in lithium stripping, leaving the lithium toward the tip isolated. These dead volumes may be fully disconnected from the electrode and become nano-lithium flotsams or partially maintain mechanical con-nection with a SEI shell tube. In either case, there will be no electric

path to the isolated lithium.

Next-generation energy storage technologies such as Li-S [70,71] and Li-air(oxygen) [72,73] batteries can greatly benefit from the use of Li metal anode. In-situ ETEM observations shed light on detailed growth, shrinkage, electrical isolation and mechanical spallation (flotsam) mechanisms of the lithium whiskers. We have also directly visualized liquid electrolyte decomposition and SEI formation. The SEI formation is a nanoscale phenomenon (irreversible side reaction) that competes with lithium metal deposition in consuming the Faradaic current, and also directly impacts the root vs. tip growth mechanism of the lithium dendrite. Electrolyte additives could modify the structure and properties of the naturally formed SEI, and thus influence the lithium dendrite instability. Since the naturally formed SEI is very thin ($\sim10^1$ nm to sub-10 nm), this would also mean that an artificial SEI surface decoration (like BN or oxide treatment) of the electrode could significantly improve the surface instability. These understanding may help to develop protrusion suppression methods over a wide range of overpotentials.

In-situ Liquid Environmental Electrochemical Cell (LEEC) experiment

We designed LEEC for in-situ transmission electron microscopy (TEM) observation of the electrochemical reactions. The cell consists of two chips (one with Au electrode and the other with $LiCoO_2$ film). These chips were fabricated on four-inch Si wafer. The procedure is schematically shown in Fig. S1. First, 70 nm Si_3N_4 membrane was deposited on a wafer. Then a current collector was deposited. Al was selected as the current collector for the chip with LCO film and Cr/Au/Cr was used for the one with Au electrode. After the Au was deposited as the electrode for Li electrodeposition, Si_3N_4 was deposited on the Au electrode outside the membrane window area as a passivation layer to prevent undesired side reactions and current consumptions during the electrochemical deposition process. For the LCO chip, LCO film was deposited on the Al current collector followed by 500 °C annealing. After electrode materials were deposited on the chip, Au/Cr spacers were deposited for securing a space for the electrolyte. Finally, the membrane window was created by Si_3N_4 backside etching → front side surface protection → silicon etching → removing protection layer. The wafer was diced to individual chips. Optical microscopy images of the chips are shown in Fig. S2, and the material selection and the thickness for the chip fabrication are summarized in Table S1. The geometry of the electrode patterned on the Si_3N_4 membrane is shown in Fig. S3. Since the thickness of the electrode is 50 nm, the surface area of the electrode is ~717 μm^2. This value is used to calculate the current density supplied to the electrode.

Since the electrolyte is injected by capillary effect, it is difficult to precisely evaluate the amount of liquid injected. However, it can be estimated by the chip geometry. Although the spacers of the chip was designed to have 250 nm thick liquid layer in the cell, the actual thickness of the typical assembled chip was ~ 1 μm. Assuming the injected electrolyte was distributed within 0.5 mm radius from the center of the window, the amount of liquid stored in the cell is

estimated to be 7.8 x 10^{-10} L. Therefore, the amount of electrolyte in the chip should be in the order of nL's.

After the cell was assembled and the electrolyte was injected, we mounted the cell on Nanofactory scanning tunneling microscopy (STM) - TEM holder for the observation. Here, gold rods were glued on the electrode pads of the cell using conducting epoxy (Circuitworks, CW2400) for mounting the cell on the holder as shown in Fig. S4. JEOL 2010F with 200 kV acceleration voltage was used for the in-situ TEM experiment.
